Results for the excited meson and baryon spectrum with two flavors of Chirally Improved sea quarks are presented. We simulate several ensembles with pion masses ranging from 250 to 600 MeV and extrapolate to the physical pion mass. Strange quarks are treated within the partially quenched approximation. Using the variational method, we investigate the content of the states. Among others, we discuss the flavor singlet/octet content of Lambda states. In general, our results compare well with experiment, in particular, we get very good agreement with the $\Lambda(1405)$ and confirm its flavor singlet nature.

1. Introduction

Given the wealth of experimental data on hadron resonances [1], an *ab initio* calculation starting from QCD would be highly desirable. Although there is a noticeable progress in calculating resonances on the lattice (for a review, see, *e.g.*, [2]), so far, most lattice calculations are restricted to the calculation of the discrete spectrum in a finite box. Towards larger volumes, the discrete spectrum become denser, and the volume dependence is related to the phase shift of the resonance in the elastic region [3, 4]. However,

in finite volume and also for unphysically heavy pion masses, the decay channels are often not open or the corresponding phase space is small. This leads to energy levels in the finite system which are close to the resonance peak, at least for narrow resonances. One thus identifies such discrete energy levels with the masses of corresponding resonances. The present article is a further contribution in this spirit. The results presented here have been published before in [5–7], for recent reviews on hadron spectroscopy on the lattice, see, *e.g.*, [8–10].

2. Setup

We use the Chirally Improved (CI) fermion action [11, 12], which is an approximate solution to the Ginsparg–Wilson equation. A parametrization of a general fermion action is taken as ansatz, and the Ginsparg–Wilson equation is solved algebraically after truncation. For the gauge sector, we use the tadpole-improved Lüscher–Weisz action [13]. The lattice spacing a is set at the physical pion mass for each value of the gauge coupling using a Sommer parameter $r_0 = 0.48$ fm, as discussed in [5]. The energy levels are determined using the variational method [14, 15]. One constructs several interpolators O_i for each set of quantum numbers and computes the cross-correlation matrix $C_{ik}(t) = \langle O_i(t) O_k(0)^\dagger \rangle$. The generalized eigenvalue problem

$$C(t)\vec{u}_n(t) = \lambda_n(t)C(t_0)\vec{u}_n(t) \quad (1)$$

yields approximations to the energy eigenstates $|n\rangle$. The exponential decay of the eigenvalues

$$\lambda_n(t) = e^{-E_n(t-t_0)} \left(1 + \mathcal{O} \left(e^{-\Delta E_n(t-t_0)} \right) \right) \quad (2)$$

is determined by the energy levels, where ΔE_n is the distance to other spectral values. The eigenvectors tell about the content of the states in terms of the lattice interpolators. We simulate two CI light sea quarks and consider a valence strange quark. The strange quark mass is fixed by setting the Ω -mass to its physical value. We generated seven ensembles of 200–300 gauge configurations with pion masses in the range from 255 MeV to 596 MeV, lattice size $16^3 \times 32$, and lattice spacing between 0.1324 and 0.1398 fm. For two ensembles with light pion masses also lattices of size $12^3 \times 24$ and $24^3 \times 48$ were used to extrapolate to infinite volume. We use a large set of interpolators in each quantum channel, combining quark sources of different smearing width, different Dirac structure and different flavor structure. For the mesons, we also use derivative quark sources to enlarge the basis and to access spin 2 and exotic channels. The interpolators are given explicitly in [5, 7]. Albeit a large basis, it includes only quark–antiquark and

3-quark interpolators. In principle, the sea quarks should provide overlap of these interpolators with meson–meson and meson–baryon states. In practice, however, we cannot clearly identify such states. A possible explanation may be a weak overlap with the used interpolators. The states may also be effectively included in the eigenstates, leading to a linear combination of exponentials in the eigenvalues. The present work is a continuation of [16], considering more ensembles, larger statistics and more observables.

3. Results

We study the light and strange baryon channels $J = 1/2, 3/2$ in both parities and the light and strange meson channels $J = 0, 1, 2$ in both parities and both C -parities. Figures 1 and 2 show our results for the energy levels in finite volume after extrapolation to physical pion mass (linear in m_π^2). In general, the low energy levels agree nicely with the experimental values, where available. As an example, we reproduce the prominent $\Lambda(1405)$. In Fig. 3 (left-hand side) we shown the corresponding results

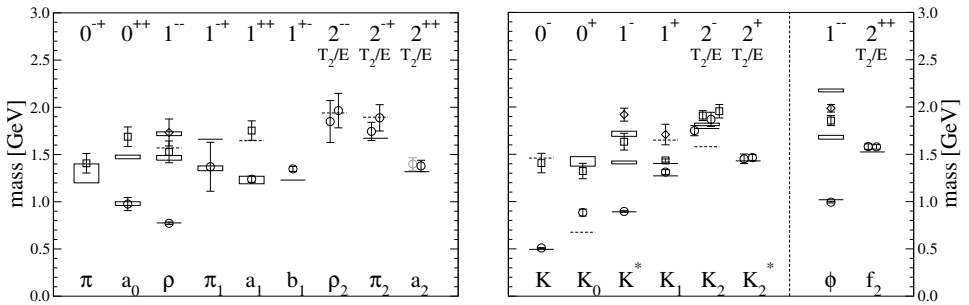

Fig. 1. Energy levels for isovector light (left), strange and isoscalar (right) mesons in finite volume. All values are obtained by chiral extrapolation linear in the pion mass squared. Horizontal lines and boxes represent experimentally known states, dashed lines indicate poor evidence, according to [1]. The statistical uncertainty of our results is indicated by bands of 1σ , that of the experimental values by boxes of 1σ . For spin 2 mesons, results for T_2 and E are shown side by side. Grey symbols denote a poor χ^2/dof of the chiral fits. Disconnected diagrams are neglected in the isoscalars channels.

for the individual ensembles. In some cases, our results suggest the existence of yet experimentally unobserved resonance states. However, some obtained energy levels mismatch experiment. One example is the first excitation in the nucleon ($J^P = 1/2^+$) channel, which is considerably higher than the Roper resonance. A possible interpretation is a weak overlap of our interpolators with the physical state. This may be also the case in the Λ ($J^P = 1/2^+$) channel, where the first excitation is dominated by singlet

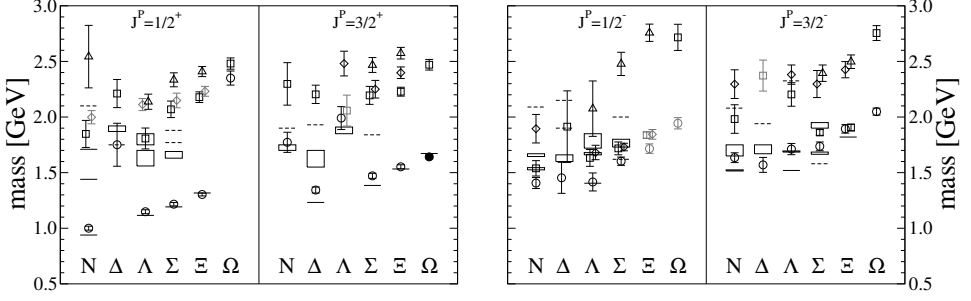

Fig. 2. As in Fig. 1, but for positive (left) and negative parity (right) baryons.

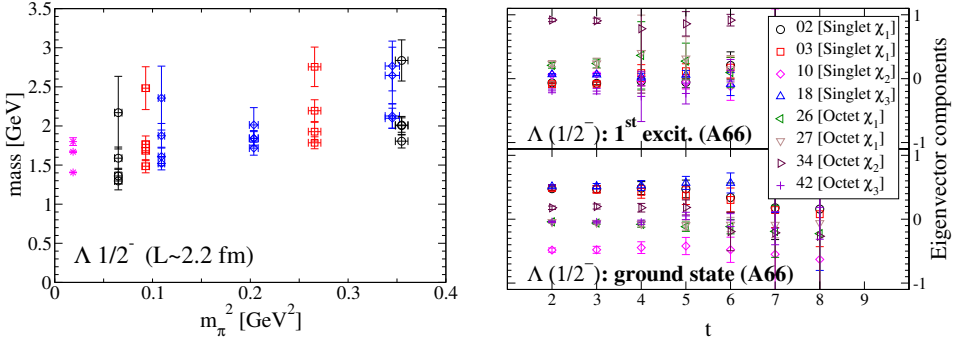

Fig. 3. Energy levels (left) and eigenvectors for the ground state and the first excitation for ensemble A66, $m_\pi \approx 255$ MeV, (right) for the baryon channel Λ ($J^P = 1/2^-$) in a finite box of linear size $L \approx 2.2$ fm. On the left-hand side, the stars (magenta) denote the experimental values [1], all other symbols represent results from the simulation. The ground state is dominated by singlet, the first excitation by octet interpolators. A considerable mixing of singlet and octet is observed (15–20% for the ground state).

interpolators matching the $\Lambda(1810)$ (singlet in the quark model), while the Roper-like $\Lambda(1600)$ (octet in the quark model) seems to be missing. We study the systematic effects due to the choice of interpolators and fit ranges and we also perform infinite volume extrapolations for several energy levels where the signal is good enough. Figure 4 shows our results for the energy levels after extrapolation to infinite volume. The origin of remaining small deviations from experiment cannot be identified uniquely in our study. In general, however, our results in the infinite volume limit compare very well with experiment. For the baryons, we analyze the flavor content by identifying the singlet/octet/decuplet contributions. For example, we find a dominance of singlet interpolators (mixing of 15–20% with octet) for $\Lambda(1405)$, and a dominance of octet interpolators of the first excitation. The

Fig. 4. As in Fig. 1, but for hadrons in the infinite volume limit.

corresponding eigenvectors are shown in Fig. 3. For the strange mesons, we analyze the content of positive and negative C -parity, which would be a good quantum number in the limit of $SU(3)$ flavor symmetry. As an example, we find a dominance of positive (negative) C -parity interpolators for the ground state (first excitation) in the strange meson channel K_1 ($J^P = 1^+$) (see Fig. 5), where also the lowest three energy levels agree well with the experiment.

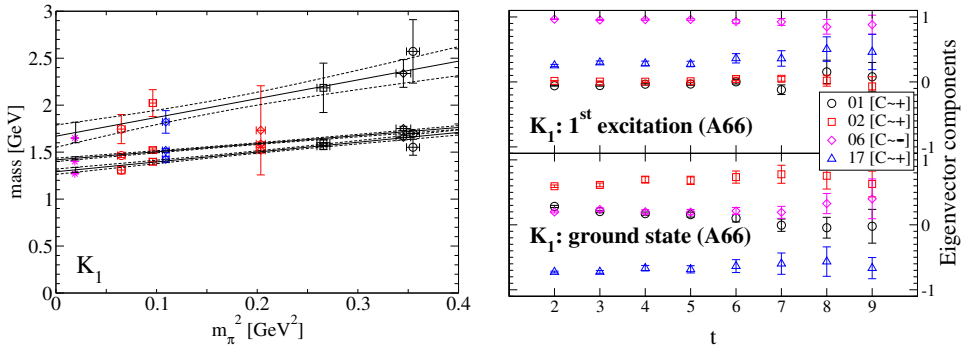

Fig. 5. As in Fig. 3, but for the strange meson channel K_1 ($J^P = 1^+$) and including a fit of the energy levels linear in m_π^2 . The ground state (first excitation) is dominated by positive (negative) C -parity, which becomes a good quantum number in the limit of $SU(3)$ flavor symmetry. Note that mixing is observed in both states.

We thank E. Gamiz, Ch. Gatttringer, L.Y. Glozman, M. Limmer, W. Plessas, H. Sanchis-Alepuz, M. Schröck and V. Verduci for valuable discussions. The calculations have been performed at the Leibniz-Rechenzentrum Munich and on clusters at the University of Graz. We thank these institutions. G.P.E. and A.S. acknowledge support by the DFG project SFB/TR-55. G.P.E. was partially supported by the MIUR-PRIN contract 20093BM-NPR. Fermilab is operated by Fermi Research Alliance, LLC under Contract No. De-AC02-07CH11359 with the United States Department of Energy.
